This document is part of the specification of the free silicon manufacturing standard for manufacturing the LibreSilicon standard logic cells¹ and related free technology nodes from the LibreSilicon project.

For this initial revision 0.1 a gate-first approach has been chosen which led to the choice of polysilicon as the gate electrode material because of the simplicity of the gate alignment. For better isolation properties of the transistors and gates in overall a box-isolation approach has been chosen. All of these choices have been made with the future scale down from the recent $1\mu m$ to smaller structure sizes. **This process is for manufacturing $1\mu m$ only!** But further releases which will have been tested with smaller structure sizes can be expected.

Libre Silicon process steps

David Lanzendörfer

July 11, 2019

The general flow chart of the overall process flow can be seen in [Figure 1](#). These process steps will be discussed within the following sections.

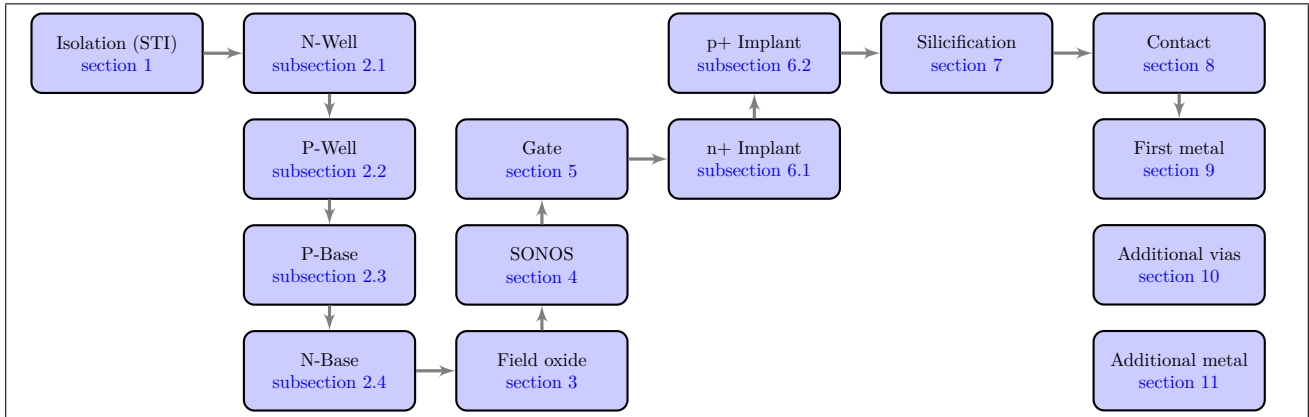

Figure 1: Frontend and backend process flow

The six overall process steps are part of an active part of the technology, while the final metal (respectively contact) layers will be used for making a contact between the logic gates and macro cells and making them available to the exterior world.

For this process p-substrate is the required basic substrate, but forks and modifications will be very well possible based on a Graphene substrate or alike, still under the LSPL. The starting material is a p-type, <100> oriented silicon with a doping concentration of $\approx 9 \times 10^{14} \text{cm}^{-3}$.

Machines required:

- Ion implanter
- Plasma etcher
- Sputter engine (Metal deposition)
- Diffusion furnace
- Exposure unit

1 Shallow trench isolation

The geometry of a substrate with STI implemented can be seen in [Figure 2](#).

Figure 2: Shallow trench isolation target geometry

As can be seen in [Figure 7](#), the n-well and the STI trench are supposed to have approximately the same depth but the n-well and p-well go down a little bit further. Because the n-well will be $\approx 4\mu m$ in depth we have to match this with our trench depth. In order to allow a sufficiently low resistance of the ESD diode but at the same time a sufficient isolation of between the standard cells a trade-off has been done. The targeted depth of the box isolation is $\approx 4\mu m$.

Figure 3: Shallow trench isolation layout

In [Figure 3](#) we can see the layout for the STI area. The STI area will be everywhere, where no well areas are. The field oxide needs to be grown out of trenches which can't be etched out of the silicon by using resist as a mask. For that reason we will have to resort to a protective mask made from a silicon dioxide layer which has to be etched before hand. So the mask will be exposed onto positive resist on top of the hard mask oxide layer in order to form a protective mask covering the active areas from having etched trenches into them. After that we can either use a dry etching method or wet etching for cutting into the silicon substrate and making the active area become islands with trenches in between. After these steps we have to remove the hard mask. Our minimum width and height as well as the space between the active areas comes from the line space constrain of the silicon etcher and of course the optical limitations of the stepper which are as well $0.5\mu m$.

1.1 Silicon etching

The trench depth has to be at least 4.5 microns deep, in order to compensate for sacrificial silicon polishing during the later CMP steps.

Figure 4: Trench etching

Typically it's a good approach to set the parameters of the DRIE recipe to an amount of cycles which will result in a depth of roughly 5 microns.

1.2 LTO+CMP

Now we trenches need to be filled up with LTO and planarized until we meet a sufficiently low height differential between the oxide surface and the silicon surface.

Figure 5: Resist removal

This process loop until a height differential below 200nm is being reached turned out to be a good approach. We start counting LTO+CMP steps at 1:

- Deposit 5 microns LTO ($\frac{5\mu}{2step-1}$)
- CMP around 5 microns LTO
- Clean in hot ammonia
- Put into buffered oxide etch or DI:HF (50:1) for one or two minutes, until silicon surface on the islands is free of oxide
- Repeat until height differential lower than 200nm

2 Tripple Well

In order to build BiCMOS on the same substrate, another N-well within the P-Base (trippel well!) is required for building the complementary isolated P-channel transistor for a n-p-channel logic circuitry as shown above in the example section.

The cross section as well as the top view of the targeted geometry are shown in [Figure 12](#)

Figure 6: Tripple well target geometry

2.1 N-well

In order to build CMOS on the same substrate, an N-well is required for building the complementary P-channel transistor for a NFET+PFET logic circuitry.

The cross section as well as the top view of the targeted geometry are shown in [Figure 7](#)

Figure 7: N-well target geometry

The N-well will serve us as an island of N-doped substrate within the P-doped basis substrate.

The P-dopant concentration of our prime grade, p-type, single side polished, four inch wafers is between $8.76 \cdot 10^{14} \frac{1}{cm^3}$ and $5.23 \cdot 10^{14} \frac{1}{cm^3}$

This means we need a dose of $2.33 \times 10^{12} cm^{-2}$ Phosphorus at 70 keV, as calculated in the documentation of the process design leading to these steps¹.

The concentration will need adjustment when the used substrate has different properties!

Figure 8: N-Well layout

In [Figure 8](#) the layout of the n-well region on top of the active area region can be seen.

The n-well is being fit into the active area. It should even be a little bit bigger than the active area, because of possible alignment offsets.

The layout is being automatically generated for GDS2 based on cifoutput rules, so you just have to draw you well.

¹https://github.com/leviathanch/libresiliconprocess/raw/master/process_design/process_design.pdf

2.2 P-well

In order to build CMOS on the same substrate, a P-well is required for building the complementary N-channel transistor for a NFET+PFET logic circuitry.

The cross section as well as the top view of the targeted geometry are shown in [Figure 7](#)

Figure 9: P-well target geometry

The "P-well" will serve us as an island of higher p-doped substrate within the slightly p-doped basis substrate and gives us more flexibility with suppliers, because we can just adjust the doping in case the concentration might be different with another supplier.

The P-dopant concentration of our prime grade, p-type, single side polished, four inch wafers is between $8.76 \cdot 10^{14} \frac{1}{cm^3}$ and $5.23 \cdot 10^{14} \frac{1}{cm^3}$

This means we need a dose of $1.93 \times 10^{12} cm^{-2}$ Boron atoms at 40 keV, as calculated in the documentation of the process design leading to these steps².

The concentration will need adjustment when the used substrate has different properties!

Figure 10: P-Well layout

In [Figure 10](#) the layout of the P-well region on top of the active area region can be seen.

The p-well is being fit into the active area.

It should even be a little bit bigger than the active area, because of possible alignment offsets.

The layout is being automatically generated for GDS2 based on cifoutput rules, so you just have to draw you well.

After the implantation we perform a drive-in in inert atmosphere at 1050°C for two hours and don't have to worry about the substrate anymore.

²https://github.com/leviathanch/libresiliconprocess/raw/master/process_design/process_design.pdf

2.3 P-base

In order to build BiCMOS on the same substrate, a nested P-well within the N-well (now it's twin well) is required for building the bijunction transistors.

The cross section as well as the top view of the targeted geometry are shown in [Figure 11](#)

Figure 11: P-base cross section

The P-base will serve us as an island of higher P-doped substrate within the slightly N-well basis substrate, which will result in a isolated area by forming PN junction versus PN junction.

The dopant dose will be $1.93 \times 10^{12} \text{cm}^{-2}$ at 40 keV, as calculated in the documentation of the process design leading to these steps³.

The P-base can very well cover the N-well area since the expansion mostly is vertical, but it should be kept in mind, that there is also a lateral diffusion when placing contacts also on N-well around the P-base.

The layout is being automatically generated for GDS2 based on cifoutput rules, so you just have to draw your P-base.

After the implantation we perform a drive-in in inert atmosphere at 1050°C for one hour.

2.4 N-base

In order to build BiCMOS on the same substrate, another N-well within the P-Base (tripple well!) is required for building the complementary isolated P-channel transistor for a n-p-channel logic circuitry as shown above in the example section.

The cross section as well as the top view of the targeted geometry are shown in [Figure 12](#)

Figure 12: N-well target geometry

The N-well will serve us as an island of N-doped substrate within the P-doped basis substrate.

The dopant dose will be $2.33 \times 10^{12} \text{cm}^{-2}$ at 70 keV, as calculated in the documentation of the process design leading to these steps⁴.

The n-well is being fit into the active area. It should even be a little bit bigger than the active area, because of possible alignment offsets.

The layout is being automatically generated for GDS2 based on cifoutput rules, so you just have to draw you well.

After the implantation we perform a drive-in in inert atmosphere at 1050°C for half an hour.

³https://github.com/leviathanch/libresiliconprocess/raw/master/process_design/process_design.pdf

⁴https://github.com/leviathanch/libresiliconprocess/raw/master/process_design/process_design.pdf

3 Field oxide

The geometry of a substrate with the field oxide filling the shallow trench from [section 1](#) now needs to be made.

Figure 13: Shallow trench isolation target geometry

As can be seen in [Figure 13](#), the STI trenches need to be filled with silicon oxide and windows need to be etched into them so that the gate can be constructed later on. The windows are needed so that the poly silicon is far enough away from the non-active areas so that the threshold voltage of the parasitic FETs is so high that they will never switch. Only within the active areas we want to allow the poly layer to touch down closer to the silicon.

During the oxidation the dopants will be further driven in which will lead to the final formation of the N-well with an approximate depth of $4\mu m$ and the P-well with an approximate depth of $5\mu m$.

3.1 Oxide growth/Drive-in

Now we need to fill the trenches with silicon dioxide which will provide a spacer between the non active area and the polysilicon gate layer. within the non-active areas.

Figure 14: Hard mask growth

We grow a roughly $1.23\mu m$ thick layer of silicon dioxide by putting the wafer into the furnace at $1050^{\circ}C$ for 4 hours and 30 minutes in a wet environment.

During the oxidation the dopants will be further driven in which will lead to the final formation of the N-well with an approximate depth of $4\mu m$ and the P-well with an approximate depth of $5\mu m$.

3.2 Etching

We open the access to the silicon inside of the active areas in order to touch down with the polysilicon further on.

Figure 15: Nitride mask etching

There are dry etching and wet etching methods available for etching the thick field oxide. The downside of wet etching is that it also etches horizontally, however the chemical BHF is readily available and allows for easy implementation of the process.

Possible approaches:

- **"AOE Etcher (DRY-AOE)" from HKUST**
We can use anisotropic plasma etching for sharper borders.
- **Chemical solution**
We can use buffered hydrofluoric acid (BOE (1:6)) at room temperature for a little bit over 3 minutes in order to get through the 300nm of oxide.
Too long over 3 minutes might cause under-etch however!

4 SONOS

Now we have to build the initial gate structure which contains of the 40nm thick dielectric (in our case just silicon dioxide) and the polysilicon electrode.

Figure 16: Poly silicon gate contacts with gate oxide

The line spacing of the polysilicon electrode shape has to be at least $0.5\mu m$ because of the resolution of the stepper and also because of the etching process which has $0.5\mu m$ as the minimum line spacing.

Figure 17: Gate layout

In [Figure 23](#) we can see the layout honoring the $0.5\mu m$ spacing design rule for the gate structure shape and poly-layer interconnect between NMOS and PMOS.

4.1 Lower oxide deposition

Now we have to deposit the dielectric isolator between the gate electrode and the channel. As designed in the process design document, the layer will be 40nm thick.

Figure 18: Thin oxide

The thickness of this layer decides over many critical key properties of the transistor, hence there should be little to no variation in the thickness of the gate oxide layer. For that reason we put the wafer into the diffusion furnace and perform dry oxidation at 1050°C for 33 minutes and 14 seconds.⁵

4.2 Silicon nitride deposition

Now we need to add the polysilicon layer for forming the gate structure after etching.

Figure 19: Polysilicon

We use the LPCVD machine and deposit a layer of around 600nm polysilicon⁶.

We set the temperature to 650°C , the gas will be Silane (SiH_4 ($\text{Si} + 2\text{H}_2$)), the pressure will be set to 300 mTorr with a flow of 90sccm.

This will give us a growth rate of roughly 23.5 nm per minute, so for 600nm we let it grow half an hour.

⁵<http://cleanroom.byu.edu/OxideTimeCalc>

⁶https://people.rit.edu/lffeee/LPCVD_Recipes.pdf

4.3 Upper oxide deposition

Now we have to deposit the dielectric isolator between the gate electrode and the channel. As designed in the process design document, the layer will be 40nm thick.

Figure 20: Thin oxide

The thickness of this layer decides over many critical key properties of the transistor, hence there should be little to no variation in the thickness of the gate oxide layer. For that reason we put the wafer into the diffusion furnace and perform dry oxidation at 1050°C for 33 minutes and 14 seconds.⁷

⁷<http://cleanroom.byu.edu/OxideTimeCalc>

4.4 Etching

Now we've got to etch the gate structures.

Figure 21: Resist

For now we only have the plasma etcher variant being verified because chemically etching polysilicon isn't allowed at the HKUST labs for contamination control reasons. In case you can verify this in your lab with a chemical etching method, please update this chapter and make a pull request!

Possible approaches:

- **"Poly Etcher (DRY-Poly)" from HKUST**

An anisotropic plasma etcher, in order to etch the polysilicon and gate oxide layer. In [subsection 5.2](#) we've grown 600nm of polysilicon which takes 200 seconds (= 3 minutes 20 seconds) (at 180nm/min) to etch. The selectivity to oxide is 13:1 which leads to an oxide etching speed of around 14nm/min, in [subsection 5.1](#) we've grown a 40nm thick oxide layer which leads to the oxide adding another 2 minutes 51 seconds to the etching time. All together, we will have to etch for around **6 minutes and 10 seconds**.

- **Chemical method**

Please add a verified method here!

5 Gate

Now we have to build the initial gate structure which contains of the 40nm thick dielectric (in our case just silicon dioxide) and the polysilicon electrode.

Figure 22: Poly silicon gate contacts with gate oxide

The line spacing of the polysilicon electrode shape has to be at least $0.5\mu m$ because of the resolution of the stepper and also because of the etching process which has $0.5\mu m$ as the minimum line spacing.

Figure 23: Gate layout

In [Figure 23](#) we can see the layout honoring the $0.5\mu m$ spacing design rule for the gate structure shape and poly-layer interconnect between NMOS and PMOS.

5.1 Gate oxide deposition

Now we have to deposit the dielectric isolator between the gate electrode and the channel. As designed in the process design document, the layer will be 40nm thick.

Figure 24: Thin oxide

The thickness of this layer decides over many critical key properties of the transistor, hence there should be little to no variation in the thickness of the gate oxide layer. For that reason we put the wafer into the diffusion furnace and perform dry oxidation at 1050°C for 33 minutes and 14 seconds.⁸

5.2 Polysilicon deposition

Now we need to add the polysilicon layer for forming the gate structure after etching.

Figure 25: Polysilicon

We use the LPCVD machine and deposit a layer of around 600nm polysilicon⁹.

We set the temperature to 650°C , the gas will be Silane (SiH_4 ($\text{Si} + 2\text{H}_2$)), the pressure will be set to 300 mTorr with a flow of 90sccm.

This will give us a growth rate of roughly 23.5 nm per minute, so for 600nm we let it grow half an hour.

⁸<http://cleanroom.byu.edu/OxideTimeCalc>

⁹https://people.rit.edu/lffeee/LPCVD_Recipes.pdf

5.3 Etching

Now we've got to etch the gate structures.

Figure 26: Resist

For now we only have the plasma etcher variant being verified because chemically etching polysilicon isn't allowed at the HKUST labs for contamination control reasons. In case you can verify this in your lab with a chemical etching method, please update this chapter and make a pull request!

Possible approaches:

- **"Poly Etcher (DRY-Poly)" from HKUST**

An anisotropic plasma etcher, in order to etch the polysilicon and gate oxide layer. In [subsection 5.2](#) we've grown 600nm of polysilicon which takes 200 seconds (= 3 minutes 20 seconds) (at 180nm/min) to etch. The selectivity to oxide is 13:1 which leads to an oxide etching speed of around 14nm/min, in [subsection 5.1](#) we've grown a 40nm thick oxide layer which leads to the oxide adding another 2 minutes 51 seconds to the etching time. All together, we will have to etch for around **6 minutes and 10 seconds**.

- **Chemical method**

Please add a verified method here!

6 Junction implants

6.1 n+ Implant

For the bulk of the PMOS transistors and for the source and drain of the NMOS transistors highly doped n+ areas are required.

In this step we're going to build these.

Figure 27: N+ implant geometry target

The tricky thing here is to have a reasonable implant depth but not too deep because the deeper the junction, the higher the junction capacity which in turn limits the switching performance of the CMOS circuitry.

Figure 28: N+ layout

An example layout of p-implants can be seen in [Figure 28](#), the mask is being extracted from the layer "n_plus_select".

The nselect is implanted with a Phosphorus (P^{31}) dose of $2.5 \times 10^{12} cm^{-2}$ at an energy of 30 keV (43nm±18nm deep)

Also important to notice is that this example layout is just for demonstration purposes only, please have a look at the standard cell documentation for the actual layouts.

6.2 p+ Implant

For the bulk of the NMOS transistors and for the source and drain of the PMOS transistors highly doped p+ areas are required. In this step we're going to build these.

Figure 29: P+ implant geometry target

The tricky thing here is to have a reasonable implant depth but not too deep because the deeper the junction, the higher the junction capacity which in turn limits the switching performance of the CMOS circuitry.

Figure 30: P+ layout

An example layout of p-implants can be seen in [Figure 30](#), the mask is being extracted from the layer "p_plus_select"

Also important to notice is that this example layout is just for demonstration purposes only, please have a look at the standard cell documentation for the actual layouts.

The pselect is implanted with a Boron (B^{11}) dose of $2.5 \times 10^{12} cm^{-2}$ at an energy of 20 keV (43nm±18nm deep)

7 Silicification

Titanium silicide is one of the first SALICIDE material introduced in ULSI devices owing to its low resistivity, high thermal stability, ease in deposition and compatibility with silicon processes. Titanium has been one of the familiar materials in ULSI productions, which is also an important advantage in practical use of titanium SALICIDE.¹⁰

Figure 31: Silicide geometry target

In order to reduce the gate contact resistance as well as the source and drain resistance and in order to provide a more effective etch stop when plasma etching the contact windows to drain, source and gate, silicide/polycide is being added to the wafer as shown in Figure 31.

The side walls¹¹ are required in order avoid short circuits between the junction and the gate.

Figure 32: Silification layout

When titanium and silicon are brought into contact and heated at temperatures above 500 °C (in the presence of excess silicon) the higher-resistivity $C49-TiSi_2$ phase forms before the low-resistivity phase.

The $C49-TiSi_2$ phase has an orthorhombic base-centered structure with 12 atoms per unit cell and a resistivity of $60 - 90 \mu\Omega - cm$.

The $C54-TiSi_2$ phase has an orthorhombic face-centered structure having 24 atoms per unit cell and a significantly lower resistivity ($12 - 20 \mu\Omega - cm$) than the $C49-TiSi_2$.

The basic formation process of titanium SALICIDE is as follows:

A thin titanium film with 20-60 nm thickness is deposited on an entire wafer with MOSFETs structure. The deposited Ti film reacts with the exposed silicon areas such as the source/drain area and polysilicon gate electrodes by the first anneal at 600-700°C in N_2 ambient. In first anneal, $C49-TiSi_2$ phase is formed. Then,

¹⁰A Study on Formation of High Resistivity Phases of Nickel Silicide at Small Area and its Solution for Scaled CMOS Devices, 07D53437, Ryuji Tomita

¹¹<http://www.fujitsu.com/jp/group/mifs/en/resources/news/library/tech-intro/process/side-wall.html>

the unreacted titanium film on the dielectric layer such as SiO_2 or SiN is selectively etched by APM (Ammonia and Hydrogen Peroxide Mixture) solution. The final step is second anneal at 800°C or above to transform high-resistivity C49- $TiSi_2$ phase to low-resistivity C54- $TiSi_2$ phase at the gate electrodes and source/drain areas.

7.1 Oxide deposition

The thickness of this CVD deposited oxide layer will be the width of the spacer after having used highly anisotropic etching in the next few steps, for this reason the thickness of the oxide decides over the distance between the silicide and the gate oxide.

We make the oxide layer 50nm thick.

Figure 33: Oxide layer

We use the machine LPCVD machine from HKUST and deposit around 50nm of silicon dioxide with the following recipe¹²:

- Temperature: 400 °C ($SiH_4 + O_2 = SiO_2 + 2H_2$)
- Pressure = 250 mTorr
- Silane (SiH_4) flow = 40sccm
- Oxygen (O_2) flow = 48sccm

This will give a rate of 7nm ($\pm 1nm$) per minute, so we deposit for roughly seven minutes (7 min).

7.2 Silicide block patterning

We now have to pattern the mask for the silicide block layer which will produce oxide wherever no silicide is not desired within active areas.

¹²https://people.rit.edu/lffeee/LPCVD_Recipes.pdf

Figure 34: Patterning (silicide block)

It is not yet clear whether we will be needing this feature in the future, which means we have not yet finally decided whether we want to keep this step and layer within our process and technology.

7.3 Spacer etching

Now we have to etch our oxide as anisotropic as possible. This means that the etching mostly only comes "from above" with a few to nearly none horizontal etching. This means the etching process only "sees" the sidewall as a "thicker layer" and starts etching downward.

Figure 35: Anisotropic etching

Possible approaches:

- "AOE Etcher" at the NFF HKUST lab

With an etching speed of 250 nm/min for thermal oxide and an oxide thickness of around 50nm etching will take around 12 seconds.

After that we will have our desired spacer geometry forming as well as any potentially resist covered area (if silicide block is being used) with sharp etches.

7.4 Titanium deposition

We deposit a layer of titanium with a thickness of around 20-60nm which will then be reacted into titanium-silicide and titanium-polycide respectively in the further steps.

Figure 36: Titanium deposition

Possible approaches:

- **"Varian 3180 Sputter (SPT-3180)" at HKUST NFF lab:**
Has has a sputter rate of around 4 nm/s for titanium.
This means we run the deposition process for around 15 seconds.

7.5 First reaction step

The deposited Ti film reacts with the exposed silicon areas such as the source/drain area and polysilicon gate electrodes by the anneal at 800°C in Argon ambient. In this annealing step the $TiSi_2$ is formed.

Figure 37: Reaction 1

The resulting $TiSi_2$ film will be around 77nm in thickness with around 20nm left on top.

7.6 Metal removal

The unreacted titanium film on the dielectric layer such as SiO_2 or SiN is selectively etched by APM (Ammonia and Hydrogen Peroxide Mixture) solution.

Figure 38: Titanium etch

After 2-3 minutes in APM, with a bit mechanical help, all the unreacted Titanium should be gone.

8 Contacts to active area

Now we have to build the first set of vias connecting the first metal layer to the active area. These vias are in the fringe between front-end and back-end process.

Figure 39: Contact geometry target

As can be seen in [Figure 39](#), the goal of this step is purely to deposit a layer of isolation oxide, get the holes into it, down to the silicide and polyside in order to form wires later on. We do not wanna etch down anywhere else than the silicide/polyside areas because these function as etch stoppers, while everywhere else we might etch further than desired with small variations in etching time which might result in a drastic variation in sheet resistance of the junctions and gate.

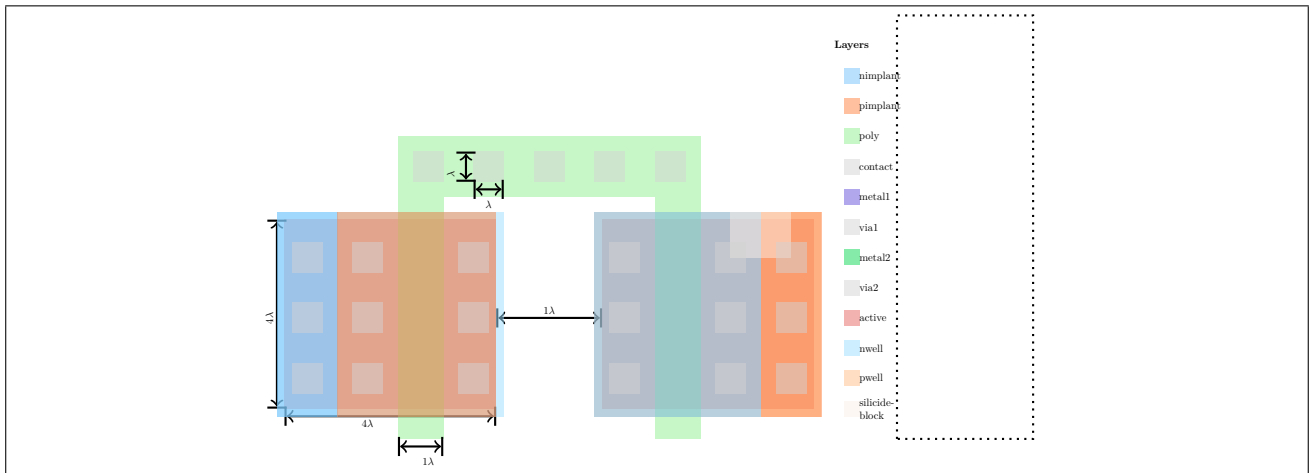

Figure 40: First via layout

It should be noted again that the via placement and dimensions in [Figure 40](#) are solely for demonstration purposes for the process and are in no way the actual standard cell design for the final standard cell lib.

In later iterations of this process we might be switching to Tungsten as the metal material for this step.

8.1 Isolation dioxide layer

We now need to grow a layer of thick oxide in order to isolate the Aluminum interconnect layer from the active area. We can't use oxide grown in from the silicon itself inside a furnace, because of the polysilicon and silicide covering the wafer. For that reason we resort to deposited LTO (low temperature oxide), which has a lower density which is even better, because of the spacing between the isolation between the metal layers is even better.

Figure 41: Oxide layer

We target a isolation layer thickness to $2\mu m$ in order to be sure that we have covered the polysilicon gate everywhere.

Possible approaches:

- **"LPCVD-B3 LTO (CVD-B3)" from HKUST**

At HKUST we have a chemical vapor deposition unit which gives us better control over the layer thickness. These steps are needed to arrive with the desired geometry¹³

1. Set the growth rate to 14 nm/min
2. Run for 140 minutes

- **In a furnace ("a hack around")**

In case of a lack of LPCVD equipment one might also resort to "hack together" a solution for LTO deposition using a furnace¹⁴

1. Deposit tetraethyl orthosilicate ($SiC_8H_{20}O_4$)
2. React for 20 minutes at $1050^\circ C$ in N_2 environment in a furnace

¹³<http://memslab.blogspot.com/2013/01/lto-lpcvd.html>

¹⁴<https://www.sciencedirect.com/science/article/pii/S0167577X89900062>

After depositing the oxide, one might wanna perform a CMP step in order to planarize the oxide surface for a more uniform deposition of metal in [subsection 9.1](#)

8.2 Etching

We now need to open a window in the dioxide layer, through which the later on deposited Aluminum will touch down onto the silicide/polycide contacts of the active area.

Figure 42: Etching contact holes

Since the silicon dioxide layer is $2\mu\text{m}$ thick and we wanna reach the silicon below we can use wet etching as described in the chemistry chapter.

Possible approaches:

- **"AOE Etcher (DRY-AOE)" from HKUST**
We can use anisotropic plasma etching for sharper borders.
- **Chemical solution**
We can use buffered hydrofluoric acid (BOE (1:6)) at room temperature ($\approx 508 \text{ nm/min}$) for around 4 minutes in order to get through the $2\mu\text{m}$ of oxide.
Too long over 4 minutes might cause under-etch however!

9 First metal layer

Now we've got to build the first interconnect wires, connecting the contact vias to the "metal1" wires, which will provide a way to contact to them with the via1 contact layout.

Figure 43: Metal geometry target

As can be seen in [Figure 43](#), the goal of this step is purely to etch the wire structure for the first metal layer into the in [subsection 9.1](#) deposited metal layer, and form wires by doing so.

Figure 44: First metal layout

It should be noted again that the via placement and dimensions in [Figure 44](#) are solely for demonstration purposes for the process and are in no way the actual standard cell design for the final standard cell lib.

In later iterations of this process we might be switching to Tungsten as the metal material for this step so the etching method might change in further releases.

9.1 Metal deposition

Now we somehow have got to get the metal onto our silicon oxide in a fashion so that it fills the holes we've etched in [subsection 8.2](#) and touches down onto the silicide/polycide, thus making a contact to the active area.

Figure 45: Metal deposition

In order to reach the target of filling the holes in the oxide and having at least another depth worth of space in order to have an enough low resistance of the wire interconnect. We end up with a target thickness of $4\mu m$.

Possible approaches:

- **"Varian 3180 Sputter (SPT-3180)" from HKUST**
The deposition speed is 16nm/s which gives us a required deposition time of 250 seconds for $4\mu m$.
- **Add your solution here!**

9.2 Etching

Now we've got to etch the Aluminum which hasn't been covered yet by the resist in order to get the desired wire structures.

Figure 46: Etching first wires

Possible approaches:

- **"Oxford Aluminum Etcher (DRY-Metal-2)" from HKUST**
The normal etch rate for Aluminum is 180 nm/min with this machines
We've deposited $4\mu\text{m}$ Aluminum in [subsection 9.1](#) which means we've got to etch for around 22 minutes and 13 seconds
- **Chemical solution**
Please specify here!

10 Via

Now we have to build an additional set of vias connecting the first metal layer to the next metal layer. These vias are already part of the front-end process.

Figure 47: Contact geometry target

As can be seen in [Figure 47](#), the goal of this step is purely to deposit a layer of isolation oxide, get the holes into it, down to the metal layer below in order to form wires later on.

Figure 48: First via layout

It should be noted again that the via placement and dimensions in [Figure 48](#) are solely for demonstration purposes for the process and are in no way the actual standard cell design for the final standard cell lib.

In a later iterations of this process we might be switching to Copper as the metal material for this step which will result in a variation of this step because the usage of damascene method.

10.1 Isolation dioxide layer

We now need to grow a layer of thick oxide in order to isolate the Aluminum interconnect layer from the active area.

Figure 49: Oxide layer

Possible approaches:

- "LPCVD-B3 LTO (CVD-B3)" from HKUST

At HKUST we have a chemical vapor deposition unit which gives us better control over the layer thickness. These steps are needed to arrive with the desired geometry¹⁵

1. Set the growth rate to 14 nm/min
2. Run for 140 minutes

- In a furnace ("a hack around")

In case of a lack of LPCVD equipment one might also resort to "hack together" a solution for LTO deposition using a furnace¹⁶

1. Deposit tetraethyl orthosilicate ($SiC_8H_{20}O_4$)
2. React for 20 minutes at 1050°C in N_2 environment in a furnace

¹⁵<http://memslab.blogspot.com/2013/01/lto-lpcvd.html>

¹⁶<https://www.sciencedirect.com/science/article/pii/0167577X89900062>

10.2 Etching

We now need to open a window in the dioxide layer, through which we will inject carrier atoms into the silicon crystal structure.

Figure 50: N+ region opened

Since the silicon dioxide layer is 100nm thick and we wanna reach the silicon below we can use wet etching as described in the chemistry chapter.

Possible approaches:

- **"AOE Etcher (DRY-AOE)" from HKUST**
We can use anisotropic plasma etching for sharper borders.
- **Chemical solution**
We can use buffered hydrofluoric acid (BOE (1:6)) at room temperature (≈ 508 nm/min) for around 4 minutes in order to get through the $2\mu\text{m}$ of oxide.
Too long over 4 minutes might cause under-etch however!

11 Additional metal layer

Now we've got to build the more interconnect wires, connecting the contact vias to the "metal2" wires, which will provide a way to contact to them with the via2 contact layout.

Figure 51: Metal geometry target

As can be seen in [Figure 51](#), the goal of this step is purely to etch the wire structure for the additional metal layer into the in [subsection 11.1](#) deposited metal layer, and form wires by doing so.

Figure 52: Second metal layout

It should be noted again that the via placement and dimensions in [Figure 52](#) are solely for demonstration purposes for the process and are in no way the actual standard cell design for the final standard cell lib.

In later iterations of this process we might be switching to Tungsten as the metal material for this step so the etching method might change in further releases.

11.1 Metal deposition

Now we somehow have got to get the metal onto our silicon oxide in a fashion so that it fills the holes we've etched in [subsection 10.2](#) and touches down onto the last metal layer, thus making a contact to the plane below.

Figure 53: Metal deposition

In order to reach the target of filling the holes in the oxide and having at least another depth worth of space in order to have an enough low resistance of the wire interconnect. We end up with a target thickness of $4\mu m$.

Possible approaches:

- **"Varian 3180 Sputter (SPT-3180)" from HKUST**
The deposition speed is 16nm/s which gives us a required deposition time of 250 seconds for $4\mu m$.
- **Add your solution here!**

11.2 Etching

Now we've got to etch the Aluminum which hasn't been covered yet by the resist in order to get the desired wire structures.

Figure 54: Etching first wires

Possible approaches:

- **"Oxford Aluminum Etcher (DRY-Metal-2)" from HKUST**
The normal etch rate for Aluminum is 180 nm/min with this machines
We've deposited $4\mu\text{m}$ Aluminum in [subsection 11.1](#) which means we've got to etch for around 22 minutes and 13 seconds
- **Chemical solution**
